What is congenital generalized lipodystrophy?

Congenital generalized lipodystrophy (also called Berardinelli-Seip congenital lipodystrophy) is a rare condition characterized by an almost total lack of fatty (adipose) tissue in the body and a very muscular appearance. Adipose tissue is found in many parts of the body, including beneath the skin and surrounding the internal organs. It stores fat for energy and also provides cushioning. Congenital generalized lipodystrophy is part of a group of related disorders known as lipodystrophies, which are all characterized by a loss of adipose tissue. A shortage of adipose tissue leads to the storage of fat elsewhere in the body, such as in the liver and muscles, which causes serious health problems.

The signs and symptoms of congenital generalized lipodystrophy are usually apparent from birth or early childhood. One of the most common features is insulin resistance, a condition in which the body's tissues are unable to recognize insulin, a hormone that normally helps to regulate blood sugar levels. Insulin resistance may develop into a more serious disease called diabetes mellitus. Most affected individuals also have high levels of fats called triglycerides circulating in the bloodstream (hypertriglyceridemia), which can lead to the development of small yellow deposits of fat under the skin called eruptive xanthomas and inflammation of the pancreas (pancreatitis). Additionally, congenital generalized lipodystrophy causes an abnormal buildup of fats in the liver (hepatic steatosis), which can result in an enlarged liver (hepatomegaly) and liver failure. Some affected individuals develop a form of heart disease called hypertrophic cardiomyopathy, which can lead to heart failure and an abnormal heart rhythm (arrhythmia) that can cause sudden death.

People with congenital generalized lipodystrophy have a distinctive physical appearance. They appear very muscular because they have an almost complete absence of adipose tissue and an overgrowth of muscle tissue. A lack of adipose tissue under the skin also makes the veins appear prominent. Affected individuals tend to have a large chin, prominent bones above the eyes (orbital ridges), large hands and feet, and a prominent belly button (umbilicus). Affected females may have an enlarged clitoris (clitoromegaly), an increased amount of body hair (hirsutism), irregular menstrual periods, and multiple cysts on the ovaries, which may be related to hormonal changes. Many people with this disorder develop acanthosis nigricans, a skin condition related to high levels of insulin in the bloodstream. Acanthosis nigricans causes the skin in body folds and creases to become thick, dark, and velvety.

Researchers have described four types of congenital generalized lipodystrophy, which are distinguished by their genetic cause. The types also have some differences in their typical signs and symptoms. For example, in addition to the features described above, some people with congenital generalized lipodystrophy type 1 develop cysts in the long bones of the arms and legs after puberty. Type 2 can be associated with intellectual disability, which is usually mild to moderate. Type 3 appears to cause poor growth and short stature, along with other health problems. Type 4 is associated with muscle weakness, delayed development, joint abnormalities, a narrowing of the lower part of the stomach (pyloric stenosis), and severe arrhythmia that can lead to sudden death.

How common is congenital generalized lipodystrophy?
Congenital generalized lipodystrophy has an estimated prevalence of 1 in 10 million people worldwide. Between 300 and 500 people with the condition have been described in the medical literature. Although this condition has been reported in populations around the world, it appears to be more common in certain regions of Lebanon and Brazil.

What genes are related to congenital generalized lipodystrophy?

Mutations in the *AGPAT2*, *BSCL2*, *CAV1*, and *PTRF* genes cause congenital generalized lipodystrophy types 1 through 4, respectively. The proteins produced from these genes play important roles in the development and function of adipocytes, which are the fat-storing cells in adipose tissue. Mutations in any of these genes reduce or eliminate the function of their respective proteins, which impairs the development, structure, or function of adipocytes and makes the body unable to store and use fats properly. These abnormalities of adipose tissue disrupt hormones and affect many of the body's organs, resulting in the varied signs and symptoms of congenital generalized lipodystrophy.

Some of the genes associated with congenital generalized lipodystrophy also play roles in other cells and tissues. For example, the protein produced from the *BSCL2* gene is also present in the brain, although its function is unknown. A loss of this protein in the brain may help explain why congenital generalized lipodystrophy type 2 is sometimes associated with intellectual disability.

In some people with congenital generalized lipodystrophy, no mutations have been found in any of the genes listed above. Researchers are looking for additional genetic changes associated with this disorder.

Related Gene(s)

Changes in these genes are associated with congenital generalized lipodystrophy.

- *AGPAT2*
- *BSCL2*
- *CAV1*
- *PTRF*

How do people inherit congenital generalized lipodystrophy?

This condition is inherited in an autosomal recessive pattern, which means both copies of the gene in each cell have mutations. The parents of an individual with an autosomal recessive condition each carry one copy of the mutated gene, but they typically do not show signs and symptoms of the condition.

Where can I find information about diagnosis or management of congenital generalized lipodystrophy?

These resources address the diagnosis or management of congenital generalized lipodystrophy and may include treatment providers.

You might also find information on the diagnosis or management of congenital generalized lipodystrophy in Educational resources and Patient support.

To locate a healthcare provider, see How can I find a genetics professional in my area? (http://ghr.nlm.nih.gov/handbook/consult/findingprofessional) in the Handbook.

Where can I find additional information about congenital generalized lipodystrophy?

You may find the following resources about congenital generalized lipodystrophy helpful. These materials are written for the general public.

- **MedlinePlus - Health information**

- **Additional NIH Resources - National Institutes of Health**
  - National Heart Lung and Blood Institute: Cardiomyopathy (http://www.nhlbi.nih.gov/health/health-topics/topics/cm/)
  - National Institute of Diabetes and Digestive and Kidney Diseases: Insulin Resistance and Pre-Diabetes (http://www.niddk.nih.gov/health-information/health-topics/Diabetes/insulin-
resistance-prediabetes/Pages/index.aspx)

What other names do people use for congenital generalized lipodystrophy?

- Berardinelli-Seip congenital lipodystrophy
- Berardinelli-Seip syndrome
- Brunzell syndrome (with bone cysts)
- BSCL
- generalized lipodystrophy
- lipodystrophy, congenital generalized
- Seip syndrome
- total lipodystrophy

What if I still have specific questions about congenital generalized lipodystrophy?

Ask the Genetic and Rare Diseases Information Center (https://rarediseases.info.nih.gov/gard).

What glossary definitions help with understanding congenital generalized lipodystrophy?
acanthosis nigricans; adipocytes; adipose tissue; arrhythmia; autosomal; autosomal recessive; cardiomyopathy; cell; cirrhosis; congenital; cysts; diabetes; diabetes mellitus; disability; gene; heart failure; hepatic; hirsutism; hormone; hypertriglyceridemia; hypertrophic; inflammation; inherited; insulin; insulin resistance; joint; lipodystrophy; liver failure; pancreas; pancreatitis; prevalence; protein; puberty; pyloric; recessive; short stature; stature; stenosis; stomach; syndrome; tissue; triglycerides; veins

You may find definitions for these and many other terms in the Genetics Home Reference Glossary.
